Abstract:

Data-acquisition systems are widely used in renewable energy source (RES) applications in order to collect data regarding the installed system performance, for evaluation purposes. In this paper, the development of a computer-based system for RES systems monitoring is described. The proposed system consists of a set of sensors for measuring both meteorological (e.g. temperature, humidity etc.) and electrical parameters (photovoltaics voltage and current etc.).

The collected data are first conditioned using precision electronic circuits and then interfaced to a PC using a data-acquisition card. The LABVIEW program is used to further process, display and store the collected data in the PC disk. The proposed architecture permits the rapid system development and has the advantage of flexibility in the case of changes, while it can be easily extended for controlling the RES system operation.

Keywords:

Renewable energy sources; Data-acquisition system; Microcomputer; Sensors; LABVIEW.

1. Introduction:

The rapid evolution of renewable energy sources (RESs) during the last two decades resulted in the installation of many RES power systems all over the world. A disadvantage of RES systems is that the installation cost is still high, so their design optimization is desirable. However, such an effort requires detailed knowledge of meteorological data of the site where the system will be installed and operational results from similar systems, if available.

Many data-acquisition systems have been developed in order to collect and process such data, as well as monitor the performance of RES systems under operation, in order to evaluate their performance [1–3]. A data-acquisition system used for monitoring the performance of both photovoltaic battery charging [4] and water-pumping systems [5] is shown in Fig. 1(a). An A/D converter interfaced to a microcontroller-based unit records a set of sensors’ signals, while the collected data are stored in a local EPROM. The data collected by the microcontroller are transmitted to a PC, with an RS-232 serial connection, where they are stored for further processing.

The same architecture has been implemented in [6–8] for solar irradiation and ambient temperature measurements. In all the above-mentioned cases, Windows or MS-DOS based software was developed specifically for each application, in order to process and display the collected data on the PC, but this approach is not flexible to changes, e.g. the addition of new sensors. A different approach has been proposed in [9], shown in Fig. 1(b). A commercial data-logging unit has been used to measure a set of meteorological and operational parameters of a hybrid photovoltaic–diesel system. The collected data are transmitted to a PC through an RS-232 serial interface, where they are processed using the LABVIEW data acquisition software. However, a data logging unit lacks flexibility compared with a data-acquisition card approach, while, in addition, it cannot be used for RES system control.

A common characteristic of the design methods described above is that a microcontroller-based data-logging unit is used to measure the signals of interest and interface the collected data to a PC through an RS-232 serial interface. However, serial data transmission limits the system performance if an advanced control capability is desired.
In this paper, a computer-based data-acquisition system for monitoring both meteorological data and RES system operational parameters is proposed. A block diagram of the proposed system is shown in Fig. 1(c). A set of sensors are used to measure atmospheric and soil conditions, as well as quantities regarding the energy produced by the hybrid photovoltaic/wind generator power system, such as the photo-voltaic array voltage and current, the wind generator speed etc. The sensor signals are first filtered and amplified using precision electronic circuits and then are interfaced to a PC, through the PCI bus, using a commercially available data-acquisition card.

The collected data are further processed, displayed on the monitor and stored in the disk using the LABVIEW software. This method has the advantages of rapid data-acquisition system development and flexibility in the case of changes, while it can be easily extended to control the RES system operation. Also, the LABVIEW provides an easy-to-use graphical environment that permits the system operators to process easily the collected data, using complex data-processing algorithms, without detailed knowledge of the data-acquisition system design [10]. The proposed data-acquisition system has been interfaced to a pilot low-power RES system just for test purposes, but this does not limit its use on large power capacity RES plants, which is the main objective of such monitoring and control systems.

This paper is organized as follows: an analysis of the sensors and the electronic circuits developed is presented in Section 2, the data collection and processing interfaces are described in Section 3 and the experimental results of the proposed design application in an operating hybrid RES system are given in Section 4.

2. The sensors and the interface circuits:

A block diagram of the RES system under consideration is shown in Fig. 2. The positions of the sensors used are also indicated in the figure. The power plant consists of two photovoltaic (PV) arrays of 450 and 300 W, respectively, and a 2 kW permanent magnet (PM) wind generator (W/G). Both the W/G and one of the PV arrays are used to charge a 24 V battery stack, by means of appropriate battery chargers. A DC/AC inverter is used to supply the load, which in this case is the lamp array of a parking lot. The second PV array is interconnected to the electric grid through a grid-connected-type inverter. The size of the above RES plant is experimental, but.

**Fig. 1. Data-acquisition architectures for RES systems:** (a) a microcontroller-based system, (b) a data-logging unit connected to a PC and (c) the proposed arrangement block diagram.

**Fig. 2. The RES system block diagram and the sensors used.**
the proposed data-acquisition system can be interfaced to larger power capacity RES plants, where the PC power consumption is negligible compared with that generated by the RES system. The voltages of both PV arrays and the W/G are measured with voltage dividers connected to an AD625 precision instrumentation amplifier [Fig. 3(a)].

In RES systems equipped with batteries as storage units, the battery service time depends on the estimated state of charge, which is highly sensitive to the current measurement errors. In such cases, if the battery charge monitoring is based on amp-hour measurements using Hall-effect sensors [11], a circuitry improving the measurement accuracy is essential, as explained below.

All currents are measured with Honeywell Microswitch CSLA1CF type Hall-effect sensors. The non-intrusive method of measurement and the very low power loss are among the advantages of this type of sensor. A disadvantage is that the zero current offset voltage has a temperature coefficient of 0.05%/C relative to the offset at 25°C.

The measurement of currents as high as 100 A dictates the use of a single wire turn wound around the magnetic core, causing relatively high errors when measuring low currents, due to the sensor temperature coefficient. Thus, the development of a temperature compensation arrangement is necessary.

The Hall-effect sensors compensation circuit developed is depicted in Fig. 3(b). The forward voltage temperature drift of a small signal diode balances the Hall-effect sensor offset voltage temperature drift.

The Hall-effect sensors compensation circuit tested in the laboratory features a temperature coefficient of \( \frac{dV}{dT} = -0.8 \text{ mV/} \text{C} \), while the compensation diode has a coefficient of \( \frac{dV}{dT} = -2.3 \text{ mV/} \text{C} \), where \( V_H \) is the Hall-effect sensor output voltage, \( V_D \) is the compensation diode voltage and \( T \) is the temperature.

\[
\frac{dV}{dT} = G_1 \frac{dV}{dT} + G_2 \frac{dV}{dT} \quad (4)
\]

The W/G rotational speed is measured using the circuit shown in Fig. 3(c). As shown in Fig.
3(d), the sinusoidal voltage between two phases of the W/G (Vac) is transformed into a TTL level digital signal (Vs) with frequency (fWG) proportional to the W/G speed. This digital signal is connected to one of the data-acquisition card counter inputs and the W/G speed is computed by means of the data-collection software, as explained in the next section.

All other atmospheric and soil condition sensor signals are amplified differentially using AD625 type instrumentation amplifiers, while the amplifier outputs are connected to the data-acquisition card analog input channels through low-pass RC filters and protection diodes, as shown in Fig. 4.

The ambient temperature and humidity are measured using the Rotronic MP100A type hygrometer, while the barometric pressure and the global irradiation are measured using the Delta-T Devices BS4 type barometer and the GS1 type pyranometer, respectively. The wind speed and direction are measured with the Vector Instruments A100R type anemometer and the W200P type wind vane, respectively. The wind speed signal is connected to a counter input of the data-acquisition card (Fig. 4).

The soil temperature is measured with a PT100 Platinum resistance RTD type sensor and the soil heat flux is measured with a Hukseflux HFP01 type heat flux plate. The soil volumetric water content is measured with the Campell Scientific CS615-L type water content reflectometer. Its output voltage period is proportional to the soil volumetric water content and is converted to an analog signal with the LM331 precision frequency-to-voltage converter (Fig. 4).

3. The data collection and processing interfaces:

The data-acquisition system uses the National Instruments PCI-6024E type DAQ card installed in a PC. All instrumentation amplifier outputs and the digital signals are connected to the card through the external CB-68-LP R686 connector block.

The DAQ card has the following operational characteristics:

- 16 single ended or eight differential analog input channels (software selectable per channel) with a ±10 V operating range;
- a successive approximation A/D converter with a 12-bit accuracy and a 200 kS/s maximum sampling rate;
- two analog output channels with 12-bit accuracy;
- eight digital input/output channels; and
- two up/down timer/counters.

The data-acquisition card is controlled by a properly developed interface, using the LABVIEW software, running on the PC. It consists of two parts: (a) a graphical environment with components such as displays, buttons and charts in order to provide a convenient-to-use environment for the system operator, and (b) the program code, which is in block-diagram format and consists of built-in virtual instruments (VIs), performing functions such as analog channel sampling, mathematical operations, file management etc. The LABVIEW software runs under the Windows 95/98/NT/2000 operating system and it requires a Pentium processor, a minimum RAM of 32 MB and 60 MB of disk storage space. The block diagram of the developed LABVIEW program is illustrated in Fig. 5. Initially, all analog signals are sequentially sampled and the input voltage data are calibrated to correspond to physical units. The calibration equations have the general form:

\[ y_i = a_i x_i + b_i \]
The soil volumetric water content is measured with the Hukseflux HFP01 type heat flux plate. The soil temperature is measured with a PT100 Platinum resistance RTD type sensor and the soil heat flux is connected to a counter input of the data-acquisition card (Fig. 4). The wind speed signal is measured using the Delta-T Devices BS4 type barometer and the global irradiation are measured using the Delta-T Devices A100R type anemometer and the GS1 type pyranometer, respectively. The wind speed is further corrected using the R30 Rotor calibration data. The corresponding correction factor F is calculated by interpolation, using a look-up table and the wind speed vlin calculated in Eq. (6). The correct wind speed va (m/s) is then derived from the following equation:

\[ v_{WG} = \frac{v_{lin}}{F} \]  

where \( v_{lin} \) is the calculated speed (m/s), \( N_a \) are the anemometer revolutions per minute (rpm), \( D \) is a conversion constant given by the anemometer manufacturer and equal to 47.7 rpm/m/s and \( f_a \) is the measured frequency (Hz).

\[ y_i = a_i x_i + b_i \]

where \( y_i \) is the ith sensor output in physical units, \( x_i \) is the ith sample and \( a_i, b_i \) are calibration constants. The frequency of the anemometer digital output signal is used for calculation of the wind speed, forming the corresponding LABVIEW built-in VI. The relation for the conversion of frequency to wind speed is the following:

\[ v_{lin} = \frac{v_{WG}}{F} \]

where \( v_{lin} \) is the calculated speed (m/s), \( N_a \) are the anemometer revolutions per minute (rpm), \( D \) is a conversion constant given by the anemometer manufacturer and equal to 47.7 rpm/m/s and \( f_a \) is the measured frequency (Hz).

The wind speed is further corrected using the R30 Rotor calibration data. The corresponding correction factor F is calculated by interpolation, using a look-up table and the wind speed vlin calculated in Eq. (6). The correct wind speed va (m/s) is then derived from the following equation:

\[ v_{WG} = v_{lin} \left( \frac{h_{WG}}{h_a} \right)^p \]

where \( v_{lin} \) is the calculated speed at the height of the anemometer ha, \( v_{WG} \) is the estimated wind speed at the turbine height hWG and \( P = 1 \) is the stability constant. The W/G rotational speed NWG is calculated from the corresponding digital signal frequency, as described in the previous section, using the following equation:

\[ v_{WG} = v_{lin} \left( \frac{h_{WG}}{h_a} \right)^p \]  

where \( v_{lin} \) is the calculated speed at the height of the anemometer ha, \( v_{WG} \) is the estimated wind speed at the turbine height hWG and \( P = 1 \) is the stability constant. The W/G rotational speed NWG is calculated from the corresponding digital signal frequency, as described in the previous section, using the following equation:

\[ v_{lin} = \frac{v_a}{f_a} \]

where \( v_a \) is the measured speed at the height of the anemometer ha, \( v_{lin} \) is the estimated wind speed at the turbine height hWG and \( P = 1 \) is the stability constant. The W/G rotational speed NWG is calculated from the corresponding digital signal frequency, as described in the previous section, using the following equation:

\[ v_{lin} = \frac{v_a}{f_a} \]  

Fig. 5. The LABVIEW measurement program flowchart.
where $NWG$ is the rotational speed (rpm), $fWG$ is the measured frequency (Hz) and $p = 8$ is the number of the W/G pole pairs. When the calibration procedure is completed, the calculated values are displayed on the monitor. Also, the measurements performed every 1 min are stored on the PC hard disk, in files named with the current date. These files contain the exact time of the measurement along with each measured parameter identification and value. The above described LABVIEW program runs continuously.

4. The experimental results:

The monitoring system together with the power system described above is installed in a small house close to the RES. The geographical location of the installation is approximately: latitude: 35.53° (35 31' 48" N); longitude: 24.06° (2403’ 35” E); altitude: 150 m (approx.) above sea level.
The measurements of all sensors described in Section 2, collected in a specific day, are illustrated in Figs. 6–8. A part of the LABVIEW program code is shown in Fig. 9. The Hall-effect sensors used are wound with a single turn, giving a sensitivity of 26 mV/A. The temperature compensation circuit, described in Section 2, was tested in the range of 20–30°C.

The zero current temperature drift measured is less than 3% of the sensor sensitivity, while if no temperature compensation is used, then the maximum zero current temperature drift, in the same temperature range, would be about 15% of the sensor sensitivity. These results verify the accuracy improvement of the Hall-effect sensor current measurements by the compensation circuit.

5. Conclusions:

Data-acquisition systems are used in RES systems in order not only to measure the meteorological conditions, but also to collect data regarding the system performance for evaluation purposes. Most present data-acquisition systems collect the data of interest and store them in a local memory until the system operator downloads them to a computer. In this paper, the development of an integrated computer-based data-acquisition system for RES plants is described. The proposed method is based on precision electronic circuits and an easy-to-use graphical environment, based on the LABVIEW program, for processing, displaying and storing the collected data. The system operator can easily process the measured parameters using any LABVIEW built-in function available. The proposed architecture has the advantages of rapid development and flexibility in the case of changes, while it can be easily extended for controlling the RES system operation.
