Median filtering is considered a popular method to remove impulse noise from images. This non-linear technique is a good alternative to linear filtering as it can effectively suppress impulse noise while preserving edge information. The median filter operates for each pixel of the image and assures it fits with the pixels around it. Therefore, it is very useful in filtering out missing or damaged pixels of the image.

The complexity in implementation of median filter is due to the large amount of data involved in representing image information in digital format. General purpose processor as an implementation option is easier to implement on but not time-efficient due to additional constraints on memory, I/O bandwidth and other peripheral devices. Full custom hardware designs like Application Specific Integrated Circuits (ASICs) provide the highest speed to application but at the same time they have very less scope for flexibility.

Digital Signal Processors (DSPs) and Field Programmable Gate arrays (FPGAs) are two choices under the category of semi custom hardware devices. These devices give a balanced solution for performance, flexibility and design complexity. DSPs are best suited to computationally intensive applications. FPGA has been chosen for our application because of its various properties. FPGAs are reconfigurable devices, which enables rapid prototyping, simplifies debugging and verification. Its parallel processing characteristic increases the speed of implementation. In section 2 details of median filter algorithm are presented. In section 3 FPGA implementation of the algorithm is discussed. In section 5 we provide the simulation results. The discussion of the implementation is concluded in the last section.

ABSTRACT:

An efficient hardware implementation of a median filter and edge detection is presented. Input samples are used to construct a cumulative histogram, which is then used to find the median. The resource usage of the design is independent of window size, but rather, dependent on the number of bits in each input sample. This offers a realizable way of efficiently implementing large-windowed median filtering, as required by transforms such as the Trace Transform. The method is then extended to weighted median filtering. The Median filter is an effective method for the removal of impulse-based noise from the images. This paper suggests an optimized architecture for filter implementation on FPGA. A 3x3 sliding window algorithm is used as the base for filter operation. Partial implementation is done via soft core processor. The designs are synthesized for a Xilinx Spartan-3 EDK.

FPGA, Median Filter, Soft Processor Core, Parallelism, Pipelining.

I.INTRODUCTION:

Digital image processing is an ever expanding and dynamic area with applications reaching out into our everyday life such as medicine, space exploration, surveillance, authentication, automated industry inspection and many more areas. In most of the cases captured images from image sensors are affected by noise. The impulse noise is the most frequently referred type of noise. This noise, commonly also known as salt & pepper noise, is caused by malfunctioning pixels in camera sensors, faulty memory locations in hardware, or errors in the data transmission.
II. FILTER ALGORITHM:

An image is stored in the form of a 2D matrix of pixel values. We have referred sliding window algorithm described by R. Maheshwari and S.P.Rao [2]. The median is defined as the middle of a group of numbers when the numbers are sorted. The group should contain odd number of elements.

For the 2D image, a standard median operation is implemented by sliding a window of odd size (e.g., 3x3 windows) over an image. A 3x3 window size is chosen which is considered effective for most commonly used image sizes. At each position of the window, the nine pixels values inside that window are copied and sorted.

The value of the central pixel of the window is replaced with the median value of the nine pixels in the window. When applied on Grayscale images, pixels are ranked for their brightness. When applied on Color scale images, the pixel whose red, green, and blue components have the smallest sum of squared differences from the color coordinates of its neighbors is then chosen to replace the central pixel of the neighborhood.

The window shifts right by one column after every clock cycle. Window-I is read in three clock cycles. To read window-II, only the fourth column has to be accessed and column two and three can be retained from the previous window.

III. ARCHITECTURE:

To build an embedded system on Xilinx FPGAs, the embedded development kit (EDK) is used to complete the reconfigurable design. Figure 1 shows the design flow.

Unlike the design flow in the traditional software design using C/C++ language or hardware design using hardware description languages, the EDK enables the integration of both hardware and software components of an embedded system. For the hardware side, the design entry from VHDL/Verilog is first synthesized into a gate-level netlist, and then translated into the primitives, mapped on the specific device resources such as Look-up tables, flip-flops, and block memories. The location and interconnections of these device resources are then placed and routed to meet with the timing constraints. A downloadable .bit file is created for the whole hardware platform.

The software side follows the standard embedded software flow to compile the source codes into an executable and linkable file (ELF) format. Meanwhile, a microprocessor software specification (MSS) file and a microprocessor hardware specification (MHS) file are used to define software structure and hardware connection of the system. The EDK uses these files to control the design flow and eventually merge the system into a single downloadable file. The whole design runs on a real-time operating system (RTOS).

IV. FILTERING CO-PROCESSOR:

There are different ways to include processors inside Xilinx FPGA for System-on-a-Chip (SoC): PowerPC hard processor core, or Xilinx MicroBlaze soft processor core, or user-defined soft processor core in VHDL/Verilog.
In this work, The 32-bit MicroBlaze processor is chosen because of the flexibility. The user can tailor the processor with or without advance features, based on the budget of hardware. The advance features include memory management unit, floating processing unit, hardware multiplier, hardware divider, instruction and data cache links etc. The architecture overview of the system is shown in Figure 2. It can be seen that there are two different buses (i.e., processor local bus (PLB) and fast simplex link (FSLbus) used in the system [5-6]. PLB follows IBMCore connect bus architecture, which supports high bandwidth master and slave devices, provides up to 128-bit data bus, up to 64-bit address bus and centralized bus Arbitration.

It is a type of shared bus. Besides the access overhead, PLB potentially has the risk of hardware/software incoherent due to bus arbitration. On the other hand, FSL supports point-to-point unidirectional communication. A pair of FSL buses (from processor to peripheral and from peripheral to processor) can form a dedicated high speed bus without arbitration mechanism. Xilinx provides C and assembly language support for easy access. Therefore, most of peripherals are connected to the processor through PLB; the DWT coprocessor is connected through FSL instead.

The current system offers several methods for distributing the data. These methods are a UART, and VGA, and Ethernet controllers. The UART is used for providing an interface to a host computer, allowing user interaction with the system and facilitating data transfer. The VGA core produces a standalone real-time display. The Ethernet connection allows a convenient way to export the data for use and analysis on other systems. In our work, to validate the DWT coprocessor, an image data stream is formed using VISUAL BASIC, then transmitted from the host computer to FPGA board through UART port.

V. OPERATIONS OF IMAGE PROCESSING:

Edge detection is the name for a set of mathematical methods which aim at identifying points in a digital image at which the image brightness changes sharply or, more formally, has discontinuities. The points at which image brightness changes sharply are typically organized into a set of curved line segments termed edges. The same problem of finding discontinuities in 1D signals is known as step detection and the problem of finding signal discontinuities over time is known as change detection. Edge detection is a fundamental tool in image processing, machine vision and computer vision, particularly in the areas of feature detection and feature extraction.

SOBEL EDGE DETECTION:

The Sobel operator is used in image processing, particularly within edge detection algorithms. Technically, it is a discrete differentiation operator, computing an approximation of the gradient of the image intensity function. At each point in the image, the result of the Sobel operator is either the corresponding gradient vector or the norm of this vector.
The Sobel operator is based on convollying the image with a small, separable, and integer valued filter in horizontal and vertical direction and is therefore relatively inexpensive in terms of computations. On the other hand, the gradient approximation that it produces is relatively crude, in particular for high frequency variations in the image.

V.EXPERIMENTAL RESULTS:

Experiments are performed on gray level images to verify the proposed method. These images are represented by 8 bits/pixel and size is $128 \times 128$. Image used for experiments are shown in below figure.

VI. CONCLUSIONS:

In this paper, a We have presented an alternative implementation of median filtering for arbitrarily large windows. The architecture is immune to changes in window size, the area being determined solely by the bit width. This allows for a flexible window-size that can change from one calculation to another and we finally presented the results which are implemented on the Spartan-3E edk evolution board.
