### ABSTRACT:

The arrival of cloud computing technology makes the storage outsourcing become a growing trend, which encourages the secure remote data auditing. Data auditing is the process of conducting a data review to measure how company's data is fit for agreed function. This engages profiling of data and assesses the collision of pitiable quality data on the organization's performance and profits. In recent times, some research believes the problem of secure with efficient public data integrity auditing for unified dynamic data. On the other hand, these systems are still not secure beside the collusion of cloud storage server as well as revoked group users during user revocation in practical cloud storage system. In this paper, we found out that the collusion attack in the exiting scheme .An efficient public integrity auditing scheme with secure group user revocation based on vector commitment plus verifier-local revocation group signature. We invented a concrete scheme.

We propose a new structure called Decrypt key, which provides efficiency and reliability assurance for convergent key management on mutually user along with cloud storage sides. The design is to apply de-duplication to the convergent keys to influence secret sharing techniques. In particular, we build secret shares for the convergent keys and share out them across multiple independent key servers.

Our proposed system rigging the public checking and efficient user revocation, as well as also some fine assets, such as confidently, efficiency, count ability and traceability.

**Key words:** Data storage, cloud storage auditing, cloud computation, key exposure resistance

### 1. INTRODUCTION:

Cloud computing can help enterprises improve the creation and delivery of IT solutions by providing them with access to services in a cost-effective and flexible manner [2]. Clouds can be classified into three categories, depending on their accessibility restrictions and the deployment model.

They are:

- Public Cloud,
- Private Cloud, and
- Hybrid Cloud.

A public Cloud is made available in a pay-as-you-go manner to the general public users irrespective of their origin or affiliation. A private Cloud's usage is restricted to members, employees, and trusted partners of the organization. A hybrid Cloud enables the use of private and public Cloud in a seamless manner. Cloud computing applications span many domains, including business, technology, government, health care, smart

grids, intelligent transportation networks, life sciences, disaster management, automation, data analytics, and consumer and social networks. Various models for the creation, deployment, and delivery of these applications as Cloud services have emerged. Cloud storage auditing is used to verify the integrity of the data stored in public cloud, which is one of the important security techniques in cloud storage. In recent years, auditing protocols for cloud storage have attracted much attention and have been researched intensively[16]. These protocols focus on numerous different characteristics of auditing, achieving high bandwidth and computation efficiency is one of the essential concerns. For that perseverance, the Homomorphic Linear Authenticator (HLA) technique that maintains block less verification is explored to diminish the overheads of computation and communication in auditing protocols, which allows the auditor to verify the integrity of the data in cloud without retrieving the whole data. Many cloud storage auditing protocols have been proposed based on this technique. In order to reduce the computational burden of the client, a third-party auditor (TPA) is introduced to help the client to periodically check the integrity of the data in cloud.

However, it is possible for the TPA to get the client's data after it executes the auditing protocol multiple times. Auditing protocols in [9] and [10] are designed to ensure the privacy of the client's data in cloud. While all existing protocols focus on the faults or dishonesty of the cloud, they have overlooked the possible weak sense of security and/or low security settings at the client. The procedure to deal with the client's secret key exposure for cloud storage auditing is a very important problem. It is focused here on how to reduce the damage of the clients key exposure in cloud storage auditing. The process involves the downloading of whole data from the cloud, producing new authenticators, and re-uploading everything back to the cloud, all of which can be tedious and cumbersome in designing a cloud storage auditing protocol with built-in key-exposure resilience. Besides,

it cannot always guarantee that the cloud provides real data when the client regenerates new authenticators.

Unswervingly espousing Standard key-evolving technique is also not suitable for the new problem setting. It can lead to repossessing all of the actual files blocks when the verification is proceeded. This is partly because the technique is incompatible with block less verification. The resulting authenticators cannot be accrued, leading to unacceptably high computation and communication cost for the storage auditing [6].

## **2. RELATED WORK:**

In order to check the integrity of the data stored in the remote server, many protocols were proposed [14] These protocols focused on various requirements such as high efficiency, stateless verification, data dynamic operation, privacy protection, etc. According to the role of the auditor, these auditing protocols can be divided into two categories: private verification and public verification. In an auditing protocol with private verifiability, the auditor is provided with a secret that is not known to the proven or other parties. Only the auditor can verify the integrity of the data. In contrast, the verification algorithm does not need a secret key from the auditor in an auditing protocol with public verifiability. Therefore, any third party can play the role of the auditor in this kind of auditing protocols. Ateniese et al. [1] firstly considered the public verification and proposed the notion of "provable data possession" (PDP) for ensuring data possession at untrusted storages. They used the technique of HLA and random sample to audit outsourced data. Juels and Kaliski Jr. explored a "proof of retrievability" (PoR) model. They used the tools of spot-checking and error-correcting codes to ensure both possession and retrievability of files on remote storage systems. Shacham and Waters [5] gave two short and efficient homomorphic authenticators: one has private verifiability which is based on pseudorandom functions; the other has public verifiability which is based on the BLS signature. Dodis et al. [31] focused on the study on different variants of existing POR work. Shah et al. introduced a TPA to keep online

storage honest. The protocol requires the auditor to maintain the state, and suffers from bounded usage. Wang et al. [10] provided a public auditing protocol that has privacy-preserving property. In order to make the protocol achieve privacy-preserving property, they integrate the HLA with random masking technique. Wang proposed a proxy provable data possession protocol. In this protocol, the client delegates its data integrity checking task to a proxy. Dynamic data operations for audit services are also attended in order to make auditing more flexible. Ateniese et al. [2] firstly proposed a partially dynamic PDP protocol. Wang et al. [11] proposed another auditing protocol supporting data dynamics. In this protocol, they utilized the BLS-based HLA and Merkle Hash Tree to support fully data dynamics. Erway et al. [13] extended the PDP model and proposed a skip list-based protocol with dynamics support. Zhu et al. proposed a cooperative provable data possession protocol which can be extended to support the dynamic auditing. Yang and Jia [9] proposed a dynamic auditing protocol with privacy-preserving property. The problem of user revocation in cloud storage auditing was considered in [15]. Most of above auditing protocols are all built on the assumption that the secret key of the client is absolutely secure and would not be exposed. But as we have shown previously, this assumption may not always be true. The current work advances the field by exploring how to achieve key-exposure resistance in cloud storage auditing, under the new problem settings.

### 3. SYSTEM DESIGN:

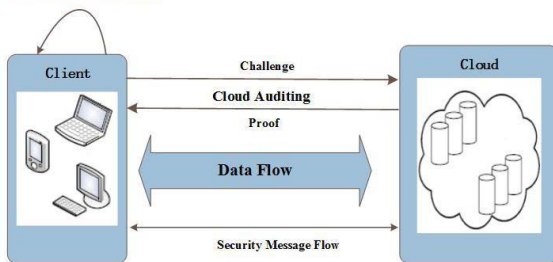

The first study has been done on how to achieve the key-exposure resilience in the storage auditing protocol and propose a new concept called auditing protocol with key-exposure resilience [4]. In such a protocol, any dishonest behaviors, such as deleting or modifying some client's data stored in cloud in previous time periods, can all be detected, even if the cloud gets the client's current secret key for cloud storage auditing [9]. This very important issue is not addressed before by previous auditing protocol

designs. We further formalize the definition and the security model of auditing protocol with key-exposure resilience for secure cloud storage. We design and realize the first practical auditing protocol with built-in key-exposure resilience for cloud storage. In order to achieve current goal, we employ the binary tree structure, seen in a few previous works [4] on different cryptographic designs, to update the secret keys of the client. Such a binary tree structure can be considered as a variant of the tree structure used in the HIBE scheme [9]. In addition, the pre-order traversal technique is used to associate each node of a binary tree with each time period. In current detailed protocol, the stack structure is used to realize the pre-order traversal of the binary tree. We also design a novel authenticator supporting the forward security and the property of block less verifiability. We prove the security of current protocol in the formalized security model, and justify its performance via concrete asymptotic analysis. Indeed, the proposed protocol only adds reasonable overhead to achieve the key-exposure resilience.

We also show that current proposed design can be extended to support the TPA, lazy update and multiple sectors. An auditing system for secure cloud storage in Fig. 1. The system involves two parties: the client (files owner) and the cloud. The client produces files and uploads these files along with corresponding authenticators to the cloud. The cloud stores these files for the client and provides download service if the client requires. Each file is furthermore divided into multiple blocks [2]. For the simplicity of description, The client can periodically audit whether his files in cloud are correct. The lifetime of files stored in the cloud is divided into  $T + 1$  time periods. In current model, the client will update his secret keys for cloud storage auditing in the end of each time period, but the public key is always unchanged. The cloud is allowed to get the client's secret key for cloud storage auditing in one certain time period. It means the secret key exposure can happen in this system model. An auditing protocol with key-exposure resilience is composed by five algorithms (Sys Setup, Key Update, Auth Gen,

Proof Gen, Proof Verify), Current security model considers the notion of the forward security [11] and data possession property [1]. In Table I, we indicate a game to describe an adversary A against the security of an auditing protocol with key-exposure resilience.

Key Update in each time period

**Fig. 1.1. System model of current cloud storage auditing**

An auditing system for secure cloud storage in Fig. 1. The system involves two parties: the client (files owner) and the cloud. The client produces files and uploads these files along with corresponding authenticators to the cloud. The cloud stores these files for the client and provides download service if the client requires. Each file is furthermore divided into multiple blocks [2]. For the simplicity of description, The client can periodically audit whether his files in cloud are correct. The lifetime of files stored in the cloud is divided into  $T + 1$  time periods . In current model, the client will update his secret keys for cloud storage auditing in the end of each time period, but the public key is always unchanged. The cloud is allowed to get the client's secret key for cloud storage auditing in one certain time period. It means the secret key exposure can happen in this system model. An auditing protocol with key-exposure resilience is composed by five algorithms (SysSetup, KeyUpdate, AuthGen, ProofGen, ProofVerify), Current security model considers the notion of the forward security [11] and data possession property [1]. In Table I, we indicate a game to describe an adversary A against the security of an auditing protocol with key-exposure resilience.

**Table 1: A game to describe an adversary against the security of the protocol**

```

Game Adversary-Forge(A)
j = 0; A ← SysSetup(PK);
Repeat
  A ← AuthGenSKj(F = (m1, ..., mn));
  SKj+1 ← KeyUpdate(SKj); j ← j + 1;
Until A goes to the break-in phase;
b = j; A ← SKb;
A ← (Chal, j* (j* < b));
P = A(Forge, F, Chal, j* (j* < b));
if ProofVerify(PK, j*, Chal, P) = 1
then return "True" else return "False".
  
```

The above security model captures that an adversary cannot forge a valid proof for a time period prior to key exposure without owning all the blocks corresponding to a given challenge, if it cannot guess all the missing blocks. In each time period prior to key exposure, the adversary is allowed to query the authenticators of all the blocks. The adversary can be given a secret key for auditing in the key-exposure (break-in) time period.

**4. PROPOSED SYSTEM:**

We firstly show two basic solutions for the key-exposure problem of cloud storage auditing before we give current core protocol. The first is a ingenious solution, which in fact cannot fundamentally solve this problem. In this solution, the client still uses the traditional key revocation method. Once the client knows his secret key for cloud storage auditing is exposed, he will revoke this secret key and the corresponding public key. Meanwhile, he generates one new pair of secret key and public key, and publishes the new public key by the certificate update[8]. The authenticators of the data previously stored in cloud, however, all need to be updated because the old secret key is no longer secure. Thus, the client needs to download all his previously stored data from the cloud, produce new authenticators for them using the new secret key, and then upload these new authenticators to the cloud[7]. The second is a slightly better solution, which can solve this problem but has a large overhead.

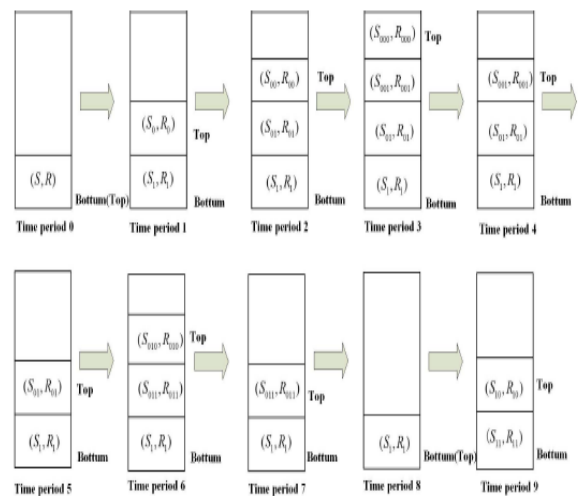

They are both impractical when applied in realistic settings. And then we give current core protocol that is much more efficient than both of the basic solutions. Current goal is to design a practical auditing protocol with key-exposure resilience, in which the operational complexities of key size, computation overhead and communication overhead should be at most sub linear to  $T$ . In order to achieve current goal, we use a binary tree structure to appoint time periods and associate periods with tree nodes by the pre-order traversal technique [14]. The secret key in each time period is organized as a stack. In each time period, the secret key is updated by a forward-secure technique [18]. It guarantees that any authenticator generated in one time period cannot be computed from the secret keys for any other time period later than this one. Besides, it helps to ensure that the complexities of keys size, computation overhead and communication overhead are only logarithmic in total number of time periods  $T$ .

As a result, the auditing protocol achieves key-exposure resilience while satisfying current efficiency requirements. As it will be shown later, in current protocol, the client can audit the integrity of the cloud data still in aggregated manner, i.e., without retrieving the entire data from the cloud. As same as the key-evolving mechanisms [11]–[13], current protocol does not consider the key exposure resistance during one time period. The public key in current protocol is denoted by  $PK$  which is fixed during the whole lifetime. In current protocol, each node of the binary tree corresponding to  $j$  has one key pair  $(Sw_j, Rwj)$ , where  $Sw_j$  is called as the node secret key which is used to generate authenticators and  $Rwj$  is called as verification value which is used to verify the validity of authenticators. The key pair of the root node is denoted by  $(S, R)$ . The client's secret key  $SK_j$  in period  $j$  is composed by two parts  $X_j$  and  $_j$ . The first part  $X_j$  is a set composed by the key pair  $(Sw_j, Rwj)$  and the key pairs of the right siblings of the nodes on the path from the root to  $w_j$ . That is, if  $w_0$  is a prefix of  $w_j$ , then  $X_j$  contains the secret key  $(Sw_1, Rw_1)$ . In current protocol, the first part  $X_j$  is organized as a stack satisfying first-in first out principle with  $(Sw_j,$

$Rwj)$  on top. The stack is initially set  $(S, R)$  in time period 0. The second part  $_j$  is composed by the verification values from the root to node  $w_j$  except the root. So  $\Omega_j = (Rwj|1, \dots, Rwj|t)$  when  $w_j = w_1 \cdot \dots \cdot w_t$ .

**Description of Current Protocol:**

- 1) SysSetup: Input a security parameter  $k$  and the total time period  $T$ . Then
  - a) Run  $IG(1k)$  to generate two multiplicative groups  $G_1, G_2$  of some prime order  $q$  and an admissible pairing  $\hat{e} : G_1 \times G_1 \rightarrow G_2$ .
  - b) Choose cryptographic hash functions  $H_1 : G_1 \rightarrow G_1, H_2 : \{0, 1\}^* \times G_1 \rightarrow Z^*$  and  $H_3 : \{0, 1\}^* \times G_1 \rightarrow G_1$ . Select two independent generators  $g, u \in G_1$ .
  - c) The client selects  $\rho \in Z^*q$  at random, and computes  $R = g\rho$  and  $S = H_1(R)\rho$ .

**Fig 1.2. An example to show the stack changes from time period 0 to time period 9 when  $l = 4$ .**

**Table 1.2: Efficiency comparison**

Protocols	SysSetup	KeyUpdate	AuthGen	ProofGen	ProofVerify
Our Protocol	$2T_e$	$4T_e$	$3T_e$	$cT_e$	$3T_p + (\log(T+2) + c + 1)T_e$
Shacham et al.'s protocol [5]	$T_e$		$2T_e$	$cT_e$	$2T_p + cT_e$

Current proposed protocol can easily be modified to support the TPA because we have considered the public verification during current design. In the modified auditing protocol supporting the TPA, the SysSetup algorithm, the Key Update algorithm and the AuthGen algorithm are the same as the description in Section 3. In the Proof Gen algorithm, we only modify current original protocol as follows: The TPA generates a challenge  $Chal = \{(i, v_i)\}_{i \in I}$ , and sends it to the cloud. After the cloud completes the same operations as those in original protocol in Section 3, it sends the proof  $P$  to the TPA instead of the client. In the Proof Verify algorithm, we only need to make the TPA instead of the client verify the validity of the tag and the proof  $P$ [19]. The block less verifiability means that the cloud can construct a proof that allows the auditor to check the integrity of certain file blocks in cloud, even when the auditor does not have access to the actual file blocks.

## 5. CONCLUSION:

In the proposed paradigm, it is deliberated on how to deal with the client's key exposure in cloud storage auditing. A new standard called auditing protocol with key-exposure resilience. The integrity of the data formerly stored in cloud can still be substantiated even if the client's current secret key for cloud storage auditing is bare in these kinds of protocols. It is enacted in the definition and the security model of auditing protocol with key-exposure resilience, and has given the practical solution. The security proof and the asymptotic presentation assessment depicted that the protocol is secure and efficient. The efficient comparison between current protocol and earlier protocol based on BLS signature also has been provided.
